Excessive amino acids in the Urine

HOSP #		**WARD**	A1 Paediatric Ward – Grey's Hospital
CONSULTANT	Prof. George van der Watt	**DOB/AGE**	27 day old Female neonate

Abnormal Result

Sodium 186mmol/L

Paed

Presenting Complaint

The neonate was taken to the Emergency Department due to seizures.

History

Unfortunately the attending clinician at Greys hospital did not have much of the history.

There was no history of diarrhoea according to what she remembered.

Examination

Patient was severely dehydrated clinically.

Later the patient presented with edema, signs and symptoms of nephropathy and biochemical changes in keeping with liver failure.

Table 2 – Urine Amino Acid results

Urine organic acids

Interpretation:
Urine organic acid analysis by GCMS demonstrates elevation of the liver markers
4-OH phenyllactate and 4-OH-phenylpyruvate together with lactaturia.
Succinylacetone, a marker for tyrosinaemia type 1 is absent. These changes
indicate underlying hepatic dysfunction with lactataemia but are non-specific
for an IMD per se. Rare forms of lactataemia include defects in pyruvate
metabolism (gluconeogenic defects such as glycogen storage disease type 1,
pyruvate dehydrogenase deficiency and thiamine deficiency). In these disorders
the lactate/pyruvate ratio is normal despite lactataemia. In pyruvate
dehydrogenase deficiency the CSF/Plasma lactate ratio is typically >2. Please
note that routine metabolic screening does not exclude galactosaemia. If
galactosaemia is suspected this should be screened for by measuring red cell
GALT activity in unspun heparin whole blood or by

screening for the common African S135L mutation in Black South African patients. As part of our gatekeeping policy to limit unnecessary testing, routine metabolic screening at Red Cross Children's Hospital consists only of urine organic and amino acid analysis. Additional tests must be requested separately based on the working differential diagnosis and routine screening results. Relevant legible clinical information also aids significantly in interpreting metabolic profiles.

Other Investigations

Urine dipstick:
Blood 3+
Protein: Trace
Glucose (by glucose oxidase) ++/+++ 28 – 55 mmol/L (hence this is most likely the predominant reducing sugar – as suggested by Prof David). This is an interesting finding since the random glucose in the ward the same day was 4.4 mmol/L. Hence two possible theories: likely either severe tubular injury or, when the child had convulsions they gave a dextrose infusion which increased the plasma glucose above the renal threshold.
pH >8.5
Nitrites: Not present
Leucocytes: Not present
Urobilirubin: Trace
Bilirubin: Not present

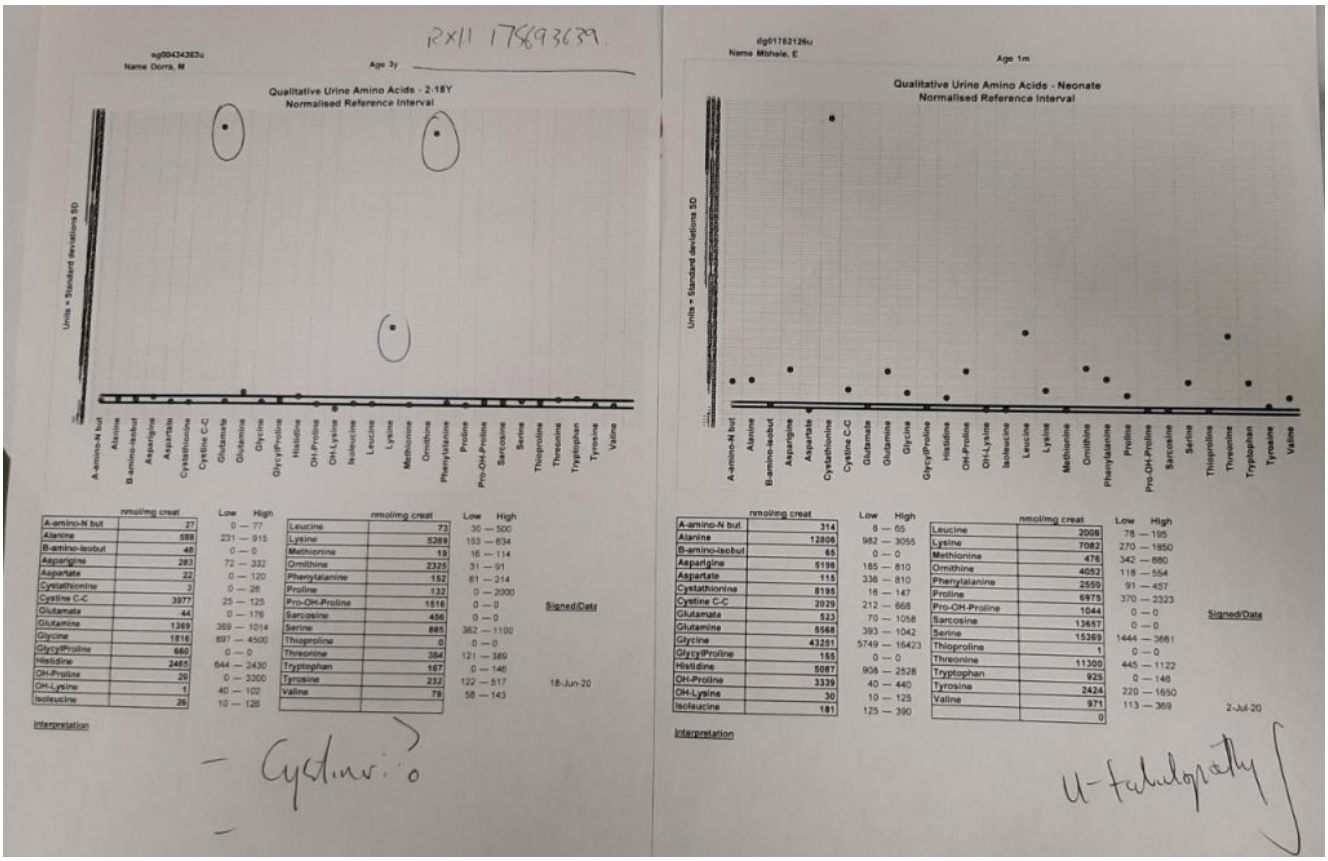
Final Diagnosis

Severe dehydration with acute kidney injury (pre-renal origin) is the most likely cause of the presentation of seizures.

Take Home Message

Dehydration is a common cause of pre-renal acute kidney injury

My thoughts initially, was that the urine amino acid screening by GCMS demonstrated a heavy generalized aminoaciduria indicative of renal tubulopathy and that cystinosis should be considered as this is the most common inheritable cause of renal tubulopathy in South Africa. However, this was later decided to be changed to rather and “evolving tubulopathy” clinical picture, as shown in the two examples below.



Typical Urine Amino acid profiles of a patient with confirmed cystinuria (left) and a patient with tubulopathy (right)

Fanconi syndrome – Generalized proximal tubular dysfunction, referred to as Fanconi syndrome, is characterized by **phosphaturia**, renal **glucosuria** (glucosuria with a normal plasma glucose concentration), **aminoaciduria**, **tubular proteinuria**, and **proximal RTA**.

The etiology of Fanconi syndrome includes inherited diseases or acquired causes [Source: Up-to-date]:

Genetic conditions associated with Fanconi syndrome include the following:

- Dent disease (X-linked recessive nephrolithiasis)
- Cystinosis
- Tyrosinemia type 1
- Galactosemia
- Wilson disease
- Lowe oculocerebrorenal syndrome, also referred to as Lowe syndrome
- Hereditary fructose intolerance
- Mitochondrial myopathies

Acquired causes of Fanconi syndrome include:

- Drugs – Medication associated with Fanconi syndrome include
    - aminoglycosides
    - cisplatin
    - ifosfamide
    - valproic acid
    - deferasirox
- Heavy metals
    - lead
    - mercury
    - cadmium

The fact that the urine dipstick was positive for glucose, suggests that either the acute kidney injury is the source of glucosuria or the patient was treated with high dose dextrose, causing the plasma glucose to overwhelm the tubular threshold for glucose transport.
